Abstract

We present a complete redesign of evaluation strategies, a key abstraction for specifying pure, deterministic parallelism in Haskell. Our new formulation preserves the compositionality and modularity benefits of the original, while providing significant new benefits. First, we introduce an evaluation-order monad to provide clearer, more generic, and more efficient specification of parallel evaluation. Secondly, the new formulation resolves a subtle space management issue with the original strategies, allowing parallelism (sparks) to be preserved while reclaiming heap associated with superfluous parallelism. Related to this, the new formulation provides far better support for speculative parallelism as the garbage collector now prunes unneeded speculation. Finally, the new formulation provides improved compositionality: we can directly express parallelism embedded within lazy data structures, producing more compositional strategies, and our basic strategies are parametric in the coordination combinator, facilitating a richer set of parallelism combinators

We give measurements over a range of benchmarks demonstrating that the runtime overheads of the new formulation relative to the original are low, and the new strategies even yield slightly better speedups on average than the original strategies.

General Terms Performance, Measurement

Keywords Parallel Functional Programming, Strategies

1. Introduction

Evaluation strategies [Trinder et al. 1998], or "strategies" for short, are a key abstraction for adding pure, deterministic, parallelism to Haskell programs. Using strategies, parallel specifications can be built up in a *compositional* way, and the parallelism can be specified *independently* of the main computation. Despite the apparent conflict between lazy evaluation and the eagerness implied by parallelism, evaluation strategies show that non-strictness

Haskell'10, September 30, 2010, Baltimore, Maryland, USA. Copyright © 2010 ACM 978-1-4503-0252-4/10/09...\$10.00 and parallelism can co-exist in a coherent programming model, and non-strictness even has some advantages for parallel languages [Loidl et al. 1999; Trinder et al. 2002]. Strategies have been used for some 15 years in a number of parallel variants of Haskell [Harris et al. 2005; Loogen et al. 2005; Trinder et al. 1998].

This paper presents a complete redesign of the strategy abstraction. Our reformulation preserves the key compositionality and modularity benefits of the original strategies (Section 4), together with their low time and space overheads (Section 6), and the formal semantics [Baker-Finch et al. 2000] is unchanged. The new formulation provides the following additional benefits:

- Clearer, more generic and more efficient specification of parallel evaluation. Describing a parallel algorithm requires specifying an order of evaluation, something which the Haskell language deliberately, and rightly, leaves unspecified. In the new strategies we introduce an *evaluation-order monad*, allowing the ordering of a set of evaluations to be specified in a perspicuous and compositional way (Section 4). Moreover, by using Applicative functors and the Traversable class [McBride and Paterson 2008], we can define generic regular strategies over data structures (Section 4.5). Our framework also supports *fusion*, which allows the intermediate lists introduced by modular strategies to be eliminated by the compiler (Section 4.8).
- The new strategies resolve a subtle space management issue where the original strategies retain heap unnecessarily (Section 3). The crux of the space management challenge is to preserve parallelism (sparks), while being able to reclaim the heap associated with superfluous parallelism. Our measurements demonstrate improved space behaviour for existing parallel programs simply by switching to the new strategies (Section 6). Furthermore, the new strategies support speculative parallelism with unnecessary speculative tasks being pruned automatically by the garbage collector, something which was not possible with the original strategies.
- There is a class of important parallel coordination abstractions that cannot be expressed as original strategies, but can be expressed in the new formulation. The feature that this class of abstractions has in common is that they all embed parallelism within lazy components of a data structure, a technique that is essential for parallelising stream-processing pipelines. In the original strategies we could write these functions, but they were not instances of the strategy abstraction and so could not be used compositionally. These drawbacks are resolved by the new framework (Section 5.1).

• Motivated by wanting to have different versions of par to control locality in large architectures, the new formulation allows for abstracting over the coordination combinator used (Section 4.4).

Sadly, however, we must all pay for our lunch, and the new formulation raises three issues.

- There is some extra complexity in the implementation of strategies. However, many casual users of the library are insulated from the changes: using and composing strategies works exactly as before, modulo some renaming. Only users who need to define their own strategies will have to become familiar with the new idioms, and there should now be fewer such users given that we provide generic strategies over any Traversable data type.
- The original strategies provided a strong *identity safety* property, namely that ('using' s) is always an identity function for any strategy s. The new strategies cannot provide the same guarantee, although the library strategies are identities, and the combinators preserve the property. Safety can be regained at the expense of expressiveness by making the strategy type abstract, giving the programmer a choice of expressiveness/safety levels (Section 5.4).
- To express control parallelism an original strategy may freely spark expressions. The corresponding new strategy must carefully preserve any sparked expressions (Section 4.6).

The new strategies are incorporated in the Haskell parallel package (Version 3.1)¹. All the code for our benchmarks is available online (Section 6), and the results were obtained with a recent GHC development snapshot (6.13 as of 20.5.2010). The latest official release, GHC 6.12.3, achieves similar speedups.

2. Original Strategies

Pure parallelism in Haskell is achieved using only two primitives, par and pseq, with the following types²:

```
par :: a -> b -> b
pseq :: a -> b -> b
```

The par combinator introduces a potential for parallel evaluation. When par is applied to two arguments, it returns the value of its second argument, while its first argument is possibly evaluated in parallel. We say "possibly", because as far as the program is concerned, the result of par a b is always b; it makes no difference to the meaning of the program whether a is evaluated in parallel or not. We should think of par as an *annotation*; it merely hints to the Haskell implementation that it might be beneficial to evaluate the first argument in parallel.

What if the computation evaluated in parallel has the value \bot , or an error? Surely then it makes a difference to the meaning of the program whether it is evaluated, or not? In fact it does not — the system is required to ensure that the semantics of par a b is always b, regardless of the value of a, \bot or otherwise. In practice, this isn't a problem for typical Haskell implementations, as a lazy computation can already have value \bot .

It is not enough to provide par alone, because generally when suggesting that something is to be evaluated in parallel, it is useful to be able to say what it is to be evaluated in parallel *with*. Haskell neither specifies nor requires a particular order of evaluation, so normally the programmer has no control over this aspect of their program's execution. In particular, the programmer has no control over when a particular call to par will be evaluated, or what will be evaluated before or after it (or indeed in parallel with it). This is the reason for pseq: a call pseq a b introduces an order-of-evaluation requirement that a be evaluated before b. The denotational semantics of pseq is

pseq a b =
$$\perp$$
 if a = \perp
= b otherwise

and the operational semantics is that a must be evaluated to weak head normal form before returning b [Baker-Finch et al. 2000].

An example to illustrate the usage of par and pseq follows, using the traditional nfib function. More examples can be found in the literature [Jones Jr. et al. 2009; Trinder et al. 1998].

The computation is shaped like a binary tree. At each node of the computation we combine par and pseq to evaluate one branch in parallel with the other branch. The pattern here is a common one: in x 'par' (y 'pseq' e), typically e involves both x and y. The effect of this pattern is to cause x to be evaluated in parallel with y. When the evaluation of y is complete, computation proceeds by evaluating e. Here the pseq is used to control *evaluation order*.

The parallelism here is independent of the number of processors; every time par is evaluated it creates a new opportunity for some work to be evaluated in parallel (a *spark*), but the implementation is free to ignore these opportunities. Indeed typical usage of par creates many more sparks than there are processors available to execute them, and the surplus sparks are simply discarded by the runtime system.

2.1 Strategies

The basic programming model described above provides the raw material for expressing parallelism in Haskell. Building on this, a Strategies module affords an abstraction layer over par and pseq to allow larger-scale parallel algorithms to be expressed.

Strategies are a remarkably simple idea. In the original formulation, a strategy is a function of type $a \rightarrow ()$ for some a:

```
type Strategy a = a \rightarrow ()
```

Thus, a Strategy may evaluate its argument either in full or in part, and it may only return () (or diverge). Crucially, using par and pseq, a strategy may specify a recipe for evaluating its argument in parallel.

Some basic strategies can be defined as follows.

```
r0 :: Strategy a
r0 x = ()
rwhnf :: Strategy a
rwhnf x = x 'pseq' ()
rnf :: NFData a => Strategy a
-- rnf is a method in the class NFData
```

r0 is a strategy that evaluates nothing of its argument, rwhnf evaluates its argument to weak-head normal form, and rnf evaluates its argument completely. The definition of rnf depends on

¹http://hackage.haskell.org/package/parallel

² The original presentation used seq rather than pseq [Trinder et al. 1998]; however, Haskell later adopted a seq operator but without the order-ofevaluation property required for parallel execution [Marlow et al. 2009]. Hence, to avoid confusion with Haskell's seq, we now use pseq for expressing sequential ordering of evaluation.

the structure of its argument, so it is defined using a type class NFData, which has to be instantiated separately for each data type (the strategies library provides instances for common types such as Booleans, Integers, lists and tuples).

Strategies are applied with the using combinator:

using :: a -> Strategy a -> a x 'using' s = s x 'pseq' x

So far we haven't presented any strategies containing actual parallelism. A simple one is parList, which applies a strategy to each element of a list in parallel:

```
parList :: Strategy a -> Strategy [a]
parList strat [] = ()
parList strat (x:xs) = strat x 'par' parList strat xs
```

The function parList illustrates the compositional nature of the strategies abstraction: it takes as an argument a strategy to apply to each list element, and returns a strategy for the whole list. The strategy argument is typically used to specify the *evaluation degree*, that is, how much each list element should be evaluated. For instance, parList rwhnf causes each spark to evaluate its list element as far as the top-level constructor, whereas parList rnf evaluates the elements completely. Various evaluation degrees between these two extremes are possible, such as evaluating the spine of a list (we'll give examples later in Section 4.7).

The parList function can also be used to illustrate the modular nature of strategies; for example:

parMap :: Strategy b -> (a -> b) -> [a] -> [b]
parMap strat f xs = map f xs 'using' parList strat

The parMap function takes a strategy strat, a function f, and a list xs as arguments and maps the function f over the list in parallel, applying strat to every element. Note how the construction of the result with map, on the left of using, is separate from the specification of the parallelism, on the right. This is a small-scale example, but the idea also scales to much more elaborate settings [Loidl et al. 1999].

The key to the modularity is lazy evaluation. The argument to a strategy can be a complex data structure with lazy components, or even a lazily-created data structure, and this allows the algorithm that creates the data structure to be separated from the strategy that specifies how to evaluate it. It's not a panacea: not all algorithms lend themselves to being decomposed in this way, and the intermediate lazy data structure has costs of its own. Nevertheless, in many cases the modularity benefits outweigh the costs, and sometimes the intermediate data structure can be automatically eliminated by the compiler (Section 4.8).

3. Space Management: Preserving Parallelism, not Garbage

In this section we describe the main problem in the original strategies formulation that prompted the redesign described in this paper. The problem we are about to describe only came to light recently [Marlow et al. 2009].

To understand the problem we need to consider how par is implemented. When the Haskell program evaluates the expression par a b, the runtime system saves a pointer to the heap node representing a in a data structure that we call a *spark pool*. For our purposes, the spark pool is simply a set of pointers to heap objects representing computations that have been sparked by par. The runtime system from time to time removes objects from the pool in order to evaluate them using idle processors, so-called lazy task creation [Mohr et al. 1990]. More details on the implementation of spark pools can be found in [Marlow et al. 2009]; the particular implementation details are not important here.

How should the storage management system, in particular the garbage collector, treat the spark pool? There are two main alternatives, which we call ROOT and WEAK respectively, following the terminology of [Marlow et al. 2009]:

- 1. **ROOT**: entries in the spark pool should be considered implicitly live. That is, the spark pool is a source of *roots* for the garbage collector.
- 2. **WEAK**: an entry in the spark pool is only alive if the object to which it points is independently reachable. That is, the spark pool contains *weak pointers* in the usual terminology.

In fact, both of these policies lead to problems with original strategies. First, let us consider WEAK, and examine how it works with the definition of parList in the previous section. The sparks created by parList are all expressions of the form strat x for some strategy strat applied to some list element x. Now, every such expression is uniquely allocated for the sole purpose of being passed to par; the spark pool will contain references to many expressions of the form strat x, and in every case, the reference from the spark pool is the only reference to that expression in the heap. So, by definition, if we adopt the WEAK policy then every spark created by parList will be discarded by the garbage collector, and we lose all the parallelism.

Moreover, there is no definition of parList that can avoid this problem. The only value that the parList strategy can return is (), so the only way that parList can create a reachable spark is by sparking part of the structure it was originally given, such as the list elements. For example, we can define a non-compositional variant of parList that works:

parListWHNF :: Strategy [a]
parListWHNF [] = ()
parListWHNF (x:xs) = x 'par' parListWHNF xs

But unfortunately we lose the compositional nature of strategies that was so appealing about the original formulation.

So what about the alternative garbage collection policy, ROOT, where we treat the spark pool as a source of roots? Considering the parList example again, the spark pool would still contain references to expressions of the form strat x in the heap, but this time all the expressions will be retained by the garbage collector, and no parallelism is lost. However, another problem arises: what happens when there are not enough parallel processors to evaluate all the sparks? The spark pool retains references to all the strat x expressions, perhaps long after each x is no longer required by the program and would otherwise be reclaimed by the garbage collector.

In an attempt to retain potential parallelism, the storage manager is retaining memory that should have been released: this is a space leak, and can and does have dramatic performance implications (we'll tell that story in Section 6.4). Even an innocuous parList or parMap can turn a program that ran in constant space into one that requires linear heap. The adverse effects tend to manifest when running parallel programs on a single processor, because there are no spare processors to evaluate the sparks and hence allow them to be removed from the spark pool. However, effects are felt even when multiple processors are available: the garbage sparks occupy space in the spark pool that could be used for real parallelism, and processors waste time evaluating garbage sparks which erodes the overall speedup achieved.

It is tempting to think that perhaps we can solve the space leak by only retaining sparks that share some data with the main program. This is difficult to achieve, however, and in any case it is not clear that it would be a robust solution to the problem: how *much* data should be shared before we consider the spark to be alive?

3.1 Fizzled Sparks

It is possible that a spark in the spark pool can refer to a computation that has already been evaluated by the program. Perhaps there were not enough processors to evaluate the spark in parallel, and another thread ended up evaluating the computation during the normal course of computing its results.

When a spark in the spark pool refers to a *value*, rather than an unevaluated computation, we say the spark has *fizzled*; this potential for parallel execution has expired [Marlow et al. 2009]. The runtime system can, and should, remove fizzled sparks from the spark pool so that the storage manager can release the memory they refer to, to avoid the mutator wasting time evaluating useless sparks, and to make more room for real potential parallelism in the spark pool.

This is all well and good, but note that in the original strategies formulation, *most sparks will never fizzle* because they are expressions of the form strat x that are unshared and hence can never be evaluated by the main program. In contrast, the sparks generated by the simpler non-compositional operation parListWHNF above can fizzle, because in that case par is applied directly to a part of the data structure, rather than to a new unshared expression, and presumably the main program will proceed by evaluating the same data structure itself.

3.2 Speculative Parallelism

Sparking ought to support *speculative* parallelism, by which we mean sparking an expression whose value is not known for certain to be eventually required by the computation as a whole. Ideally, speculative parallelism should be automatically *pruned* by the system when it can be proven to be never needed.

Speculative parallelism can be created using par; the question is whether speculative sparks are ever discarded. Under the ROOT policy, a speculative spark that is never evaluated will become a space leak, whereas under the WEAK policy unreachable speculative sparks will be discarded and their heap reclaimed. In short, only the WEAK policy supports speculation.

3.3 Summary

For reference, the following table summarises the interaction between the choice of strategy abstraction (orginal strategies, Section 2, versus new strategies, Section 4), nature of parallelism (speculative or not), and GC policy (ROOT versus WEAK).

Strategies	Parallelism	ROOT	WEAK
original	non-speculative	space leaks	lost parallelism
original	speculative	space leaks	lost parallelism
new	non-speculative	OK	OK
new	speculative	space leaks	OK

4. A New Formulation of Strategies

The difficulties with managing the space behaviour of sparks described in Section 3 are rooted in the choice of the type for strategies: if a strategy is a function returning the unit type (), then there is no way for it to spark new expressions and to return them to the caller, thus ensuring that the sparked expressions remain reachable from the caller's heap.

The key idea in our reformulation is that a strategy returns a *new version* of its argument, in which the sparked computations have

been embedded. For example, when sparking a new parallel task of the form strat x, rather than discarding this expression, the strategy will now build a new version of the original data structure with strat x in place of x. The caller will consume the new data structure and discard the old, so that the parallel task strat x remains reachable as long as the consumer requires it. Furthermore, if the consumer evaluates strat x before it is evaluated by a parallel thread, then the spark fizzles; superfluous parallelism is discarded by the garbage collector, which is exactly what we need.

Perhaps our strategies should be identity functions. However, the simplest identity type, $a \rightarrow a$, is not a suitable strategy type candidate. Functions of this type are necessarily strict³, so we cannot express r0, the strategy that performs no evaluation of its argument, as a function of this type. To accommodate r0, the result must be lifted. We use a trivial lifting, Eval, and provide a way to unlift, runEval:

```
type Strategy a = a -> Eval a
```

```
data Eval a = Done a
```

runEval :: Eval a -> a
runEval (Done a) = a

The rationale for the names will become clear shortly. Now we can define some basic strategy combinators using the new type:

```
r0 :: Strategy a
r0 x = Done x
rseq :: Strategy a
```

```
rseq x = x 'pseq' Done x
```

rpar :: Strategy a rpar x = x 'par' Done x

```
rdeepseq :: NFData a => Strategy a
rdeepseq x = rnf x 'pseq' Done x
```

The new basic strategies r0, rseq and rdeepseq are analogues to the original strategies r0, rwhnf and rnf respectively (in fact, rdeepseq uses the original rnf).

4.1 The Evaluation-order Monad

We can declare Eval to be a monad. There are two choices here: either it is the standard identity monad, or it is a strict identity monad. The latter turns out to be a much more useful choice:

```
instance Monad Eval where
  return x = Done x
  Done x >>= k = k x
```

The strict identity monad⁴ gives us a convenient and flexible notation for expressing evaluation order, i.e. the ordering between applications of rseq and rpar, which is exactly what we need for expressing basic parallel evaluation. For example, the following fragment of nfib

```
let
    x = nfib (n-1)
    y = nfib (n-2)
in
    x 'par' (y 'pseq' x + y + 1)
can be rewritten as
runEval $ do
    x <- rpar (nfib (n-1))
    y <- rseq (nfib (n-2))</pre>
```

 $^{^3}$ such functions may only return their argument or \perp , hence when applied to \perp the result is always \perp

⁴ this is in fact isomorphic to the Lift monad in the MonadLib package, http://hackage.haskell.org/package/monadLib

```
data Eval a = Done a
                                                       instance Monad Eval where
                                                         return x = Done x
                                                         Done x >>= k = k x
                                                       runEval :: Eval a -> a
                                                       runEval (Done a) = a
type Strategy a = a \rightarrow ()
                                                       type Strategy a = a -> Eval a
using :: a -> Strategy a -> a
                                                       using :: a -> Strategy a -> a
x 'using' s = s x 'pseq' x
                                                       x 'using' s = runEval (s x)
                                                       dot :: Strategy a -> Strategy a -> Strategy a
                                                       s2 'dot' s1 = s2 . runEval . s1
r0 :: Strategy a
                                                       r0 :: Strategy a
r0 x = ()
                                                       r0 x = return x
rwhnf :: Strategy a
                                                       rseq :: Strategy a
rwhnf x = x 'pseq' ()
                                                       rseq x = x 'pseq' return x
rnf :: NFData a => Strategy a
                                                       rdeepseq :: NFData a => Strategy a
-- rnf is a method in the class NFData
                                                       rdeepseq x = rnf x 'pseq' return x
                                                       rpar :: Strategy a
                                                       rpar x = x 'par' return x
seqList :: Strategy a -> Strategy [a]
                                                       evalList :: Strategy a -> Strategy [a]
seqList s []
              = ()
                                                       evalList s [] = return []
seqList s (x:xs) = s x 'pseq' (seqList s xs)
                                                       evalList s (x:xs) = do x' <- s x
                                                                              xs' <- evalList s xs
                                                                              return (x':xs')
parList :: Strategy a -> Strategy [a]
                                                       parList :: Strategy a -> Strategy [a]
parList s []
                                                       parList s = evalList (rpar 'dot' s)
                = ()
parList s (x:xs) = s x 'par' (parList s xs)
```

Figure 1. Like-for-like comparison of original strategies (left column) versus new strategies (right column).

return (x + y + 1)

which clearly expresses the ordering between rpar and rseq, using a notation that Haskell programmers will find familiar.

Programmers using the new strategies API no longer need to use par and pseq to construct new strategies, instead they use the Eval monad with rpar and rseq. The Eval monad raises the level of abstraction for pseq and par; it makes fragments of evaluationorder first class, and lets us compose them together. We should think of the Eval monad as an Embedded Domain-Specific Language (EDSL) for expressing evaluation order, embedding a little evaluation-order-constrained language inside Haskell, which does not have a strongly-defined evaluation order.

Figure 1 summarises the differences between the API for the original strategies and the new strategies. Note that we have redefined a few combinators using the monadic style consistently, using return in place of Done, for example.

4.2 Eval, applicatively

An evaluation order is often something we want to impose on an existing expression. Since Eval is a monad, it is also an Applicative functor [McBride and Paterson 2008]:

```
instance Functor Eval where
fmap f x = x >>= return . f
instance Applicative Eval where
pure x = return x
(<*>) = ap
```

This means that we can use applicative notation for threading "evaluation order" through an expression. Here's a simple example: in one of our benchmarks (*Coins* in Section 6.3), a result value is defined as

```
res = append left right
```

and we want to spark left in parallel with right. We could use the monadic syntax as we did for the nfib example above, but sometimes even the monadic syntax is too heavy, and obscures the structure of the original code. The Applicative operators <\$> and <*> let us rewrite the expression to include the parallelism, without losing its structure:

```
res = runEval $ append <$> rpar left <*> rseq right
```

One might object that this is not a *modular* specification of parallelism, and that would be a fair criticism. However, note that apart from the introduction of rpar and rseq, the translation to applicative style is mechanical, so this is a minimal and yet precise way to add a little parallelism to an existing expression. We will discuss how to recover modularity in cases like this in Section 4.6.

Applicative notation fixes the ordering to be depth-first, so in cases where depth-first is not appropriate the monadic syntax has to be used.

4.3 Using Strategies

As with the original strategies, a strategy application operator is provided:

```
using :: a -> Strategy a -> a
```

x 'using' s = runEval (s x)

The using function is defined to have lowest precedence and associate to the left, that is e 'using' s1 'using' s2 stands for (e 'using' s1) 'using' s2. This stacking of strategies being similar to the stacking of function applications, there is a strategy composition dot such that

(e 'using' s1) 'using' s2 = e 'using' (s2 'dot' s1)

Just like function composition, dot has highest precedence and associates to the right, so the parentheses can be dropped from the above equation.

4.4 Compositional Strategies over Data

We build strategies over data types by first constructing a basic strategy for the data type, parameterised over strategies for the components of the type. The basic strategy traverses the data type in the Eval monad, applies the argument strategies to the components (usually in depth-first order), and builds a new instance of the type.

As an example, consider the Strategy combinator evalList, which walks over a list and applies the argument strategy s to every element:

The evalList combinator generalises both parList and seqList of original strategies, and more besides⁵. For example, parList is obtained by composing the element strategy s with rpar:

```
parList :: Strategy a -> Strategy [a]
parList s = evalList (rpar 'dot' s)
```

The original strategies had a seqList combinator, whereas the new strategies do not provide a seqList. In fact, evalList is the new strategies' equivalent to seqList, but it is not immediately obvious why this should be so — seqList is defined in terms of pseq, but there is no pseq to be found in the definition of evalList. The purpose of seqList is to apply the strategy s to each element of the list in left-to-right order, and it achieves this ordering by using pseq at each step. In evalList, we achieve the same ordering, but by using the Eval monad instead: the Eval monad explicitly sequences the application of the strategy s to each list element in order — pseq is no more required.

We can specialise evalList in more ways. A number of new parallel primitives are envisioned, for instance, a *bounded* par that restricts locality, e.g. a spark with a low bound should be executed "nearby". An advantage of the new strategies is that all these primitives can be passed as parameters, thus avoiding code replication.

4.5 Generic Strategies

The Traversable class provides a convenient way to thread any Applicative computation through the components of a data structure in a depth-first manner, performing any effects on the way whilst building a new data structure [McBride and Paterson 2008]. This is exactly what we need for defining strategies over regular data structures such as lists and trees: a means of traversing the data structure using Eval, applying a strategy at the leaves, and building a new structure to return.

The method traverse has the following type:

```
traverse :: (Traversable t, Applicative f)
=> (a \rightarrow f b) \rightarrow t a \rightarrow f (t b)
```

This function is so generic it is not immediately obvious how it can be applied in our setting. However, if we specialise $a \rightarrow f b$ to Strategy a, then we get:

This is a generic parameterised strategy for any Traversable data type. It has evalList as an instance, and gives us strategies for types like Maybe and Array for free. Adding parallelism to the generic strategy is straightforward:

4.6 Modularity

The key modularity property we have is that e 'using' s is observably equivalent to e, at least in so far as it is defined (the former may be less defined than the latter). The point of this guarantee is that someone who only wants to understand the algorithm can ignore the strategies, i.e. every 'using' s.

Of course, this property is only useful in cases where we can actually make use of using. Some of the examples we have already seen are not easily expressed with using; consider for example nfib from Sections 4.1:

runEval \$ do
 x <- rpar (nfib (n-1))
 y <- rseq (nfib (n-2))
 return (x + y + 1)</pre>

This kind of parallelism is known as *control* or task parallelism, where the parallelism follows the control structure of the program. However, we cannot consider this a modular specification of parallelism, as it clearly interleaves the algorithm with the coordination.

We can write a modular version:

```
x + y + 1 'using' strat
where
  x = fib (n-1)
  y = fib (n-2)
  strat v = do rpar x; rseq y; return v
```

This strategy looks odd. We aren't using the result of rpar, which should raise the red flags: normally the result of rpar should be embedded in the result returned, otherwise the spark is likely to be discarded by the garbage collector, or become a space leak. However, it is acceptable to discard the result of rpar if the argument is a variable, and that variable is already shared by the result, as it is in this case.

This is a somewhat subtle rule-of-thumb, and the user may well prefer the original direct definition using runEval. Note that the same technique was possible with original strategies, although there we had no option to use the more direct runEval style. This technique will be applied to a more realistic example in Section 5.3.

4.7 Sequential Strategies

An important class of strategies specify only evaluation degree, i.e. do evaluation only, and introduce no parallelism. Since they create no sparks, there is no need for these strategies to rebuild the data structure that they are passed. For example, if we were to define a strategy that evaluates a list sequentially as

```
forceList = evalList rseq :: Strategy [a]
```

⁵ evalList is a specialisation of the mapM associated with the Eval monad, as an anonymous reviewer observed.

then the result is a strategy that is not only needlessly inefficient, but worse, may overflow the stack on long lists because evalList is not tail-recursive⁶.

Hence we dedicate a separate module Seq to the class of strategies that do evaluation only. These *sequential strategies* have type Seq.Strategy, the same type as the original strategies:

```
type Seq.Strategy a = a \rightarrow ()
```

We make Seq.Strategy into a "subtype" of Strategy by providing an explicit upcast evalSeq, which evaluates a sequential strategy before returning the evaluated argument into the Eval monad.

```
evalSeq :: Seq.Strategy a -> Strategy a
evalSeq ss x = ss x 'pseq' return x
```

Basic sequential strategies and sequential strategy combinators are similar to the respective orginal strategies and combinators; for example:

```
r0 :: Seq.Strategy a
r0 x = ()
rseq :: Seq.Strategy a
rseq x = x 'seq' ()
seqList :: Seq.Strategy a -> Seq.Strategy [a]
seqList ss [] = ()
seqList ss (x:xs) = ss x 'seq' seqList ss xs
```

As the order of evaluation of substructures is irrelevant here, these combinators may use the ordinary Haskell seq operator instead of pseq, granting the compiler more freedom to optimise the order of evaluation. In contrast, the upcast evalSeq must use pseq to force evaluation of the sequential strategy *before* returning.

Finally, seqFoldable is the sequential strategies' counterpart to the generic strategy evalTraversable.

seqFoldable *strictly* applies a strategy to all elements of a data structure. Given the simpler return type of sequential strategies, seqFoldable is already applicable to all Foldable data structures, which form a super class of the Traversable data structures.

Sequential strategies are widely used. The example below transposes a list of matrices mats, each represented as a list of lists, in parallel without evaluating the matrix elements. The sequential strategy seqList (seqListr0) evaluates just the shape of a matrix while the parMap computes the parallel transpose:

parMap (evalSeq (seqList (seqList r0))) transpose mats

The detailed control of evaluation degree provided by sequential strategies may also be useful for tuning sequential programs. In effect the module Seq complements existing abstractions provided by the module DeepSeq.

4.8 Fusion

Using strategies in a modular way often implies that an intermediate data structure is generated by the computation, filtered by the strategy, and finally consumed upstream. Consider once again parMap:

parMap :: Strategy b -> (a -> b) -> [a] -> [b]
parMap s f xs = map f xs 'using' parList s

The list produced by map is consumed by parList, which generates another list to return to the caller of parMap. Furthermore, there is an extra traversal: both map and parList traverse the complete list.

Ideally we would like to have this intermediate structure and the extra traversal eliminated by the compiler. Fortunately, using GHC it is almost trivial to arrange that this optimisation occurs: GHC provides user-defined transformation rules, which are used to implement list fusion between many of the standard list-producing and consuming library functions. Our parList is defined in terms of parTraverse, which is defined in terms of traverse, and the list instance of traverse happens to be defined in terms of foldr. The intermediate list between map and foldr is automatically removed by GHC's transformation rules, so in fact parMap compiles to an efficient single-traversal loop.

The measurements we report in Section 6 are without the benefit of fusion. Separate measurements with fusion enabled, which require an extra annotation in the Data.Traverse library, exhibited a small improvement in speedup of +1.40% across most of the applications. Since the overhead of data structure traversal in strategies is fairly small (see Section 6.2) we cannot expect a major improvement from this conceptually important optimisation.

5. Advanced Strategies

This section discusses how advanced features such as clustering, buffering and parallel patterns, can be expressed in the new strategies. Such features are essential for real parallel applications, and are used in the kernels measured in Section 6.3.

5.1 Embedded Strategies: Rolling Buffers

Some parallel abstractions that are important for parallel performance tuning rely on embedding parallelism inside a lazy data structure, such that opportunities for parallel evaluation are created "on demand" by the consumer of the data structure. The most commonly encountered example is a parallel buffer [Trinder et al. 1998]:

parBuffer :: Int -> Strategy a -> Strategy [a]

Informally the idea is that parBuffer n s xs yields a list in which evaluation of the *i*th element induces parallel evaluation of the (i + n)th element with the first n elements being evaluated in parallel immediately. The result list must therefore be lazy, at least beyond the first n elements.

In the original strategies, while the parBuffer functionality could be defined perfectly well, it could not be expressed as a strategy, because it returns a new list containing parallelism embedded in the lazy components. That is, the original type was

parBuffer :: Int -> Strategy a -> [a] -> [a]

This was an unfortunate wart, because it meant that parBuffer could not be used as the argument to a strategy combinator and thus compositionality was diminished.

Fortunately embedded parallelism can be directly expressed in the new strategy formulation, and so parBuffer and functions like it are instances of the Strategy type.

A fully compositional implementation of parBuffer can be found below. It implements a rolling buffer (with amortised constant overhead) by means of a highly optimised functional queue data structure provided by module Data. Sequence. The rolling buffer functionality is provided by roll, which takes a functional queue (the buffer) and a list of elements yet to go into the buffer, and returns a list (via the Eval monad). Whenever the result list is demanded, roll applies the strategy s to the first element z to go into the buffer and sticks the result to the end of the queue (by calling q |> z'). Then it pulls the first element y' out at the front of

⁶ One would typically not use parList on long lists as too many sparks would be created, instead parBuffer tends to be more practical.

the queue (by matching viewl (...) against y': <q') and returns it as the head of the result list while embedding the recursive call into the tail of the result list.

```
parBuffer :: Int -> Strategy a -> Strategy [a]
parBuffer n s = evalBuffer n (rpar 'dot' s)
```

5.2 Clustering

When tuning the performance of parallel programs it is often important to increase the size of parallel computation, i.e. to use a coarser granularity, in order to achieve a better ratio of computation versus coordination costs. Implementations often contain mechanisms to automatically use coarser granularity on loaded processors. The scenario of fizzling sparks discussed in Section 3.1 is such an example, because the work of a spark is performed by an already running computation. However further improvements can be obtained by explicitly controlling thread granularity, and in the context of the original strategies we developed a range of clustering techniques [Loidl et al. 2001]. This section adapts these techniques for the new strategies and extends them.

One way to obtain a coarser granularity is to collect computations on related elements of a data structure into "clusters." To this end, we define a class Cluster containing cluster and decluster methods, as well as a method lift that turns an operation over the original data structure into one over such a clustered data structure.

```
class (Traversable c, Monoid a) => Cluster a c where
  cluster :: Int -> a -> c a
  decluster :: c a -> a
  lift :: (a -> b) -> c a -> c b
  lift = fmap -- c is a Functor, via Traversable
  decluster = fold -- c is Foldable, via Traversable
  -- we require: decluster . cluster n == id
```

By assuming the Traversable and Monoid contexts we get several operations for free. Through the implicit Functor context, we can use fmap to lift an operation over the base type to one in the cluster type. And through the Monoid and Foldable contexts (the latter implicit), we can use fold as the default for decluster provided it is an inverse of cluster.

As an example we provide an instance for lists, clustered into lists of lists. Notably, we only have to provide a definition for the cluster method.

```
instance Cluster [a] [] where
  cluster _ [] = []
  cluster n xs = ys:cluster n zs
    where (ys,zs) = splitAt n xs
```

We aim to define a strategy combinator

```
evalCluster :: Cluster a c
=> Int -> Strategy a -> Strategy a
```

which takes a cluster size parameter and generically transforms a strategy by performing clustering and declustering behind the scenes (using the methods of appropriate Cluster instances). Unfortunately, the cluster type c shows up only in the class context, which means it could be ambiguous — in fact, it should be: there may well be multiple reasonable ways of clustering a given type. To disambiguate the cluster type, we need to expose c in the signature of evalCluster by passing it as an extra argument (which requires wrapping it with a fresh type variable w). This extra argument serves purely as a "type parameter"; it is never evaluated and will be optimised away by the compiler.

Thanks to the Traversable context (inherited from Cluster), we can lift the strategy s to a strategy cs which is applicable to the clustered input. Note that the type annotation in the where clause necessitates the explicit forall in the signature.

With this infrastructure we can define a generic parMapCluster, a variant of parMap performing *implicit clustering* (based on the Cluster class) behind the scenes.

Observe how a type annotation is used to emulate passing the (wrapped) cluster type c as a "type argument" to evalCluster; the double underscore __ is short for the bottom value undefined.

To improve readability, instead of wrapping the type argument with fresh type variables, we can use a properly named phantom type:

data ClusterWith :: (* -> *) -> *

Now it is intuitive that parMapCluster (__ :: ClusterWith []) uses lists for clustering.

5.3 A Divide-and-conquer Pattern

One of the main strengths of strategies is the possibility of constructing abstractions over patterns of parallel computation. Thereby all code specifying the coordination of the program is confined to the pattern. Concrete applications can then instantiate the function parameters to get parallel execution for free. Such patterns are commonly known as algorithmic skeletons [Cole 1988].

As an example we give the implementation of a divide-and-conquer pattern. It is parameterised by a function that specifies the operation to be applied on atomic arguments (f), a function to (potentially) divide the argument into two smaller values (divide), and a function to combine the results from the recursive calls (conquer). Additionally, we provide a function threshold that is used to limit the amount of parallelism, by using a sequential strategy for arguments below the threshold.

```
divConq :: (a -> b)
                              -- compute the result
                              -- the value
       -> a
        -> (a -> Bool)
                              -- par threshold reached?
        -> (b -> b -> b)
                              -- combine results
       -> (a -> Maybe (a,a)) -- divide
        -> b
divConq f arg threshold conquer divide = go arg
  where
    go arg =
       case divide arg of
        Nothing -> f arg
         Just (10,r0) -> conquer 11 r1 'using' strat
       where
        11 = go 10
        r1 = go r0
        strat x = do r l1; r r1; return x
                  where r | threshold arg = rseq
```

| otherwise

= rpar

All coordination aspects of the function are encoded in the strategy strat, which describes how the two subcomputations 11 and r1 should be evaluated. The thresholding predicate threshold provided by the caller places a bound on the depth of parallelism, and this is used by strat to decide whether to spark both 11 and r1 or to evaluate them directly. The definition of divConq achieves separation between the specifications of algorithm and parallelism, the latter being confined entirely to the definition of strat.

5.4 Improving Safety

The original strategy type $a \rightarrow ()$ embodies the key modularity goal of separating computation and coordination. As any original strategy can only ever return (), it can never change the result of a computation, up to divergence. Unfortunately, the new strategy type gives up this type safety. Strategies of the new type $a \rightarrow Eval a$ should be identity functions, i.e. only evaluate their argument but never change its value; we term this property *identity safety*. However the type system cannot enforce this behaviour and it is all too easy to accidentally write flawed strategies, for instance:

```
x:xs 'using' \ _ -> parList rdeepseq xs
```

The intention of the programmer is to evaluate the tail of the list in parallel when the list is demanded. The strategy will do that, but then returns only the tail of the list.

We propose a way of trading expressiveness for type checked identity safety. For this purpose, the module SafeStrategies⁷ clones the functionality and interface of Strategies, except for wrapping the strategy type with a newtype and providing an explicit strategy application operator.

newtype Strategy a = MkStrat (a -> Eval a)

```
($$) :: Strategy a -> a -> Eval a
(MkStrat strat) $$ x = strat x
```

By hiding the constructor MkStrat when importing the module SafeStrategies, programmers can choose to treat Strategy as an abstract type, thereby restricting themselves to use only strategies constructed by the pre-defined and trusted (identity safe) strategy combinators (like evalList and evalTraversable). Since MkStrat is not available, the type checker will prevent programmers from "hand-rolling" their own strategies (e.g. the flawed strategy above will be rejected), thereby eliminating the danger of accidentally violating identity safety.

Yet, programmers can still use the Eval monad freely. For instance, the non-modular example of task parallelism from Section 4.6 can be ported to SafeStrategies by inserting \$\$ after rpar and rseq. Of course, careless use of rpar may cause space leaks or lost parallelismn, depending on the GC policy (Section 3), but that is a lesser concern than identity safety because it does not compromise functional correctness.

Why does SafeStrategies export the constructor MkStrat at all, rather than making Strategy a proper abstract type? The reason is that programmers who do need to "hand-roll" their own strategies may want to wrap them in MkStrat. Thus, MkStrat marks the pieces of code where programmers incur "proof obligations" to establish identity safety.

6. Evaluation

This section discusses our measurements in detail, but first we summarise the key results:

• For all programs, the speedup and runtime results with original and new strategies are very similar, giving us confidence that

they specify the same parallel coordination for a range of programs and parallel paradigms (Figure 2).

- The speedups achieved with the new strategies are slightly better compared to those with the original strategies: a mean of 4.96 versus 4.83 on 7 cores across all applications (Columns 3 & 2 of Table 2).
- The new strategies fix the space leak outlined in Section 3, reducing heap residency on a single core by 56.43% across all applications, and better support speculative parallelism (Section 6.4).
- The overheads of the new strategies are low: mean sequential run-time overhead is 3.84% (Table 1), and memory overheads are low for most programs (Columns 8 11 of Table 2).

6.1 Apparatus

Our measurements are made on an eight-core, 8GB RAM, 6MB L2 cache, HP XW6600 Workstation comprising two Intel Xeon 5410 quad-core processors, each running at 2.33GHz. The benchmarks run under Linux Fedora 7 using a recent GHC development snapshot (6.13 as of 20.5.2010), and parallel packages 1.1.0.1 and 3.1.0.0, for original and new strategies, respectively. The data points reported are the median of 3 executions. We measure up to 7 cores as measurements on the eighth core are known to introduce some variability.

Our benchmarks are 10 parallel applications from a range of application areas; 8 of these have been taken from existing benchmarks suites [Aswad et al. 2009; Loidl et al. 1999; Marlow et al. 2009] and 2 benchmarks, *Coins* and *TransClos*, have been developed afresh with the new strategies module. The programs are the computational kernels of realistic applications, cover a variety of parallel paradigms, and employ several important parallel programming techniques, such as thresholding to limit the amount of parallelism generated, and clustering to obtain coarser thread granularity.

Genetic aligns RNA sequences, using divide-and-conquer parallelism and nested data parallelism. MiniMax performs an alphabeta search in a 2-player game tree, using divide-and-conquer parallelism and exploiting laziness to prune unnecessary subtrees. Queens solves the n-queens problem, using divide-and-conquer parallelism with an explicit threshold. LinSolv finds an exact solution to a set of linear equations, employing the data parallel multiple homomorphic images approach. Hidden performs hidden-line removal in 3D rendering and uses data parallelism via the parList strategy. Maze searches for a path in a 2D maze and uses speculative data parallelism. Sphere is a ray-tracer from the Haskell nofib suite, using nested data parallelism, implemented as parMaps. TransClos finds all elements that are reachable via a given relation from a given set of seed values, using a parBuffer strategy over an infinite list. Coins computes the number of ways of paying a given value from a given set of coins, using divide-and-conquer parallelism. MatMult performs matrix multiplication using data parallelism with implicit clustering.

6.2 Sequential Overhead

Table 1 shows the sequential runtime as baseline, and the difference of the 1 processor runtime with both original and new strategies. For the new strategies, we encounter a runtime overhead of at most +18.14% for the *MatMult* program, which is mainly due to the additional work in performing clustering. For all other programs the strategy overhead is significantly lower. Notably, the data parallel programs have a fairly low overhead, despite the additional traversal of a data structure to expose parallelism. Comparing the geometric mean of the runtime overheads imposed by both strategy

⁷ currently not distributed with the parallel package

Program	Seq.	Δ Time (%)			
	Runtime	Original	New	Paradigm	
	(seconds)	Strategies	Strategies		
LinSolv	23.40	+0.90	+1.97	Nested Data par	
TransClos	83.12	+0.77	+2.24	Data par

Maze	40.93	-2.22	-3.59	Nested Data par	
Geom. Mean		+3.21	+3.84		

Table 1. Sequential runtime overheads.

versions we encounter only a slightly higher overhead for the new strategies: +3.84% compared to +3.21% with the original strategies. This justifies the new strategy approach of high-level generic abstractions.

6.3 Parallel Performance

Speedups: Figure 2 compares the absolute speedup curves (i.e. speedup relative to sequential runtime) for the applications with the original and new strategies. Both the runtime curves (not reported here) and speedup curves for the original and new strategies are very similar. The pattern is repeated in more detailed analysis, e.g. in Columns 2 and 3 of Table 2. We conclude that the original and new strategies specify the same parallel coordination for a variety of programs representing a range of parallel paradigms, and several tuning techniques.

Performance: Table 2 analyses in detail the speedups, number of sparks and memory consumption of all applications, running on 7 cores of an 8 core machine with the original strategies and the new strategies, always using a ROOT garbage collection policy. The number of generated sparks was in all cases virtually identical between original strategies and new strategies, giving us further confidence that the two formulations are expressing the same parallelism. Small differences in the number of generated sparks arise because GHC has a non-deterministic execution model in which a particular expression may be evaluated multiple times at runtime [Harris et al. 2005].

In the cases where the new strategies exhibit poorer performance, the reduction in speedup is still very small: from 5.67 to 5.48 in the worst case for *MiniMax*. This reflects the low overhead associated with the new strategies, quantified in the previous sub-section.

In the case of *MatMult* heap residency roughly doubles with the new strategies. This is due to the new strategies composing the clusters to return the result value. The original strategies only use the clusters to express parallelism, but do not compose them into the final result. Despite the higher residency, however, the new strategies achieve a higher speedup.

Interestingly, the performance of the new strategies in the *Queens* and *Sphere* programs is better than in the original strategies. Examining the heap consumption reveals that with the new strategies the heap residency is significantly reduced: -24.11% for *Queens* and -14.53% for *Sphere*. This results in a lower total garbage collection time, which contributes to about half of the reduction in runtime. The reduction in residency is accounted for by the improved space behaviour of the new strategies: the space retained by superfluous sparks is being reclaimed.

Granularity improvement: The comparison of generated versus converted sparks in Table 2 demonstrates the runtime system's ef-

fective handling of potential parallelism (sparks). Even when an excessive number of sparks is generated, for example in *Coins*, the runtime-system converts only a small fraction of these sparks. As with any divide-and-conquer program, a thread generated for a computation close to the root will itself evaluate potential child computations, causing their corresponding sparks to fizzle. Hence the granularity of the generated sparks is automatically made coarser, reducing overheads, as can be seen from the speedups achieved. In general, the new strategies provide more opportunities for sparks to fizzle, as discussed in Section 3. This shows up in a lower number of converted sparks for all divide-and-conquer and nested data parallel programs. For single-level data parallelism as in *Sphere*, where sparks never share graph structures, there is little or no reduction in the number of converted sparks.

6.4 Memory Management

Fixing the space leak: The new strategies fix the space leak outlined in Section 3. For example, for the parallel raytracer that exhibited the space leak⁸ with the original strategies, the heap residency drops from 1.6GB to 5.8MB with the new strategies on 1 core, and the runtime correspondingly drops by about a factor of 3. Comparing single core executions for all benchmark programs shows a mean reduction in residency of 56.43% with the new strategies. However, for multiple cores the heap measurements in Table 2 do not show a consistent reduction in residency for the new strategies. There are a number of factors contributing to the observed behaviour here:

- with parallel processors available, garbage sparks tend to be evaluated by other cores and hence fizzle, avoiding the space leak (but wasting some cycles);
- parallel evaluation itself tends to change the residency profile, in most cases increasing the residency compared to sequential execution;
- residency is recorded by sampling and hence the measured value is noisy.

Speculation: To assess the effectiveness of the garbage collection policies ROOT and WEAK, described in Section 3, for managing speculation we use a program that applies drop to a parallelised list, computing the number of primes up to a given value, thereby rendering the sparks on the dropped list elements speculative:

```
sum $ drop ((m1-m0) 'quot' 2) $
    ([ length (primes n) | n <- [m0..m1] ]
        'using' parList rdeepseq)</pre>
```

With the WEAK policy almost all sparks of the original strategies are discarded, as expected. With the new strategies 3404 out of 10001 are converted, 32% fewer than with the ROOT policy, although this value changes considerably between executions. Most importantly, the WEAK policy prunes 4796 sparks, almost all of the 5000 speculative sparks. In contrast, the ROOT policy prunes only 3193 sparks, all of them due to fizzling.

Only two of our application kernels use speculation: *MiniMax* and *Maze*. In the case of *MiniMax* the WEAK policy significantly reduces the variation of residencies over the number of cores, and in a 7-core execution residency is reduced by 83.4%. In the case of *Maze* residency remains unchanged. In both cases the speedup improves only slightly when employing a WEAK policy. Of course, the very inability of reclaiming speculative sparks with the ROOT policy discouraged any applications using them on a larger scale.

7. Related Work

Parallel functional languages [Hammond and Michaelson 1999] typically embed high level coordination languages into high level computation languages. A range of high level coordination models have been used [Trinder et al. 2002], and this section relates the *semi-explicit* approach adopted by evaluation strategies to other approaches.

Skeleton based coordination, for instance [Loogen et al. 2005] or [Michaelson et al. 2005], is popular in both imperative and functional languages, and exploits a small set of predefined skeletons. Each skeleton is a polymorphic higher-order function describing a common coordination pattern with an efficient parallel implementation [Cole 1988]. As polymorphic higher-order functions, evaluation strategies are similar to skeletons, but there are some key differences. Rather than a fixed set of skeletons, evaluation strategies are readily combined to form new strategies. Moreover, where skeletons are parameterised with computational arguments, a strategy is typically applied to a computation.

Data parallel coordination, as in [Blelloch 1996] or implemented in Data Parallel Haskell [Chakravarty et al. 2007], supports the parallel evaluation of every element in a collection. This is a good match with Haskell's powerful constructs for bulk data types, in particular lists. Data parallelism is often more implicit than evaluation strategies: the programmer simply identifies the collections to be evaluated in parallel. Strategies are more general in that they can express both control parallelism and data parallelism, although in terms of performance Data Parallel Haskell is designed to compile parallel programs down to highly optimised low-level loops over arrays, and hence should achieve significantly better absolute performance on data-parallel programs than would be possible using strategies.

Entirely *implicit* coordination aims to minimise programmer input, typically using either profiling as in [Harris and Singh 2007] or parallel iteration as in [Grelck and Scholz 2003]. Few entirely implicit approaches other than parallel iteration have delivered acceptable performance [Nikhil and Arvind 2001]. Evaluation strategies provide more general parallel coordination than loop parallelism.

Recent work by [Prabhu et al. 2010] has shown that parallelism by speculating on future data dependencies can be provided as a safe (correctness-preserving) abstraction to programmers. As one might expect, their approach translates naturally into Haskell using par. This approach to speculation is complementary to the speculative parallelism afforded by strategies.

8. Conclusion

The original strategies were developed in 1996 for Haskell 1.2, i.e. before monads, and using a compiler with relatively tame optimisations. The context for the new strategies is radically different. Monads, supported by rich libraries and syntactic sugar like do-notation, are now the preferred mechanism for sequencing computations, and are familiar to the rapidly growing Haskell user community. Applicative functors elegantly encode data structure traversals. Finally, the aggressive use of optimisations in mature Haskell im-

plementations like GHC make bespoke efficiency specialisations unnecessary.

The new strategy formulation capitalises on improved Haskell idioms and implementations to provide a modular and compositional notation for specifying pure deterministic parallelism. While it has some minor drawbacks: being relatively complex, providing relatively weak type safety, and requiring care to express control parallelism, the advantages are many and substantial. It provides clear, generic, and efficient specification of parallelism with low runtime overheads. It resolves a subtle space management issue associated with parallelism, better supports speculation, and is able to directly express parallelism embedded within lazy data structures.

The new strategies are available as part of the Haskell parallel package (since Version 3); additional code and benchmarks can be downloaded from http://www.macs.hw.ac.uk/~dsg/gph/papers/abstracts/new-strategies.html.

We plan to further enhance and formalise the identity safety of the new strategies, following the direction discussed in Section 5.4. Moreover the genericity of the new strategies could be improved by automatically deriving instances of the NFData class.
